2. Project management

- In what follows, we consider production processes where only a single item of a specific product is produced in the planning horizon
- In this case specific instruments for planning and controlling are necessary to enable an efficient reliable execution
- The production of the single item itself can be interpreted as a project to be managed

Business Computing and Operations Research WINFOR 108

2. Outline of the chapter

- 1. Basic definitions
- 2. Analysis of the project structure
- 3. Time analysis and planning
- 4. Analysis of the time table flexibility

Business Computing and Operations Research WINFOR 109

2.1 Basic definitions

Definition 2.1.1 (Project – according to DIN)

According to DIN 69901, a project is

- "an endeavor characterized entirely and essentially by
- specific terms, for example its objective, temporal, human or other resource limitations
- differences from other endeavors
- a project-specific organization"

Project model in this course Definition 2.1.2 (Project – in the course) As a project we define a finite set of tasks (procedures) whose processing consumes a predefined period of time and whose execution has to fulfill predefined time schedule restrictions. These restrictions can consist in specific minimal and maximal temporal distances of the beginning of tasks. Additionally, the total execution time of the project is restricted. Business Computing and Operations Research WINFOR 111

1. Description of the project Informal and formal definition of the total project Computation of the available resources Assignment of competences Integration into the existing organization 2. Analysis of the project Structure analysis Task Decomposition of the total project Determination of the existing precedence restrictions between the different tasks | Business Computing and Operations Research | WINFOR | 112

2. Time analysis Determination of the task processing times Determination of the existing time restrictions between the different tasks 3. Analysis of the capacity and material requirements 4. Cost analysis 3. Planning of the project structure Mapping of the total project in a model, e.g., Network plan Linear program

Project schedule II

Project schedule III

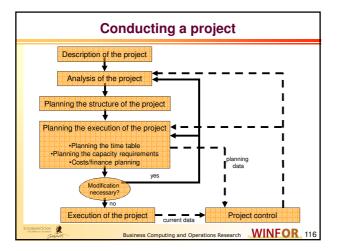

4. Time planning

- 1. Determination of feasible time tables
 - Determination of the earliest possible starting and ending positions of tasks
 - Determination of the latest possible starting and ending positions of tasks
 - Determination of the shortest possible project duration
- 2. Analysis of the flexibility of the given time table
 - Determination of the range of alternative starting positions of each task
 - Estimating the consequences of exceeding the existing time windows for each task

Business Computing and Operations Research WINFOR 114

Project schedule IV

- Planning the capacity and material requirements Optimal use of the existing capacities
- 6. Planning the resulting costs
- 7. Control of the project execution
 - 1. Controlling the consequences of costs
 - 2. Controlling the time tables
 - 3. Controlling the execution of the tasks

2.2 Analysis of the project structure

Definition 2.2.1 (Project task network)

A **project task network** V is a connected network with N+2 nodes $\{0,1,...,N,N+1\}$ and without cycles of positive length with two additional marked nodes 0 and N+1 and the following interpretation:

- 0 is the exclusive source of the network symbolizing the beginning of the total project
- $N\!\!+\!1$ is the exclusive sink of the network symbolizing the end of the total project
- Each node i (1≤i≤N) represents a task with a predefined processing time p_i
- Each edge (i,j) in the network has a weight $c_{i,j}$ that is interpreted as follows:
 - c_i≥0: The task j can begin at least c_{ij} time units after the beginning of task i (minimum distance restriction)
 - $c_{i,j}$ <0: The task i must begin at most $-c_{i,j}$ time units after the beginning of task j (maximum distance restriction)

Business Computing and Operations Research WINFOR 117

Distance requirements • Minimum distance restriction The beginning of task j has to respect a distance of at least c_{ij} time units to the beginning of task *i*. p_i denotes the processing time of task i Maximum distance restriction The beginning of task *i* has to respect a maximum distance of at most -c_{i,j} time units to the beginning of task *j* Attention: Changed orientation

Business Computing and Operations Research WINFOR 118

Business Computing and Operations Research WINFOR 119

Notation: In each time table the beginning of task i is denoted by t_i Generally, the project start is set to 0: $t_0 = 0$.
Sought: Feasible time tables
Corollary 2.2.2: Let V be a project task network with an edge (i,j) with weight $c_{i,j}$. For every time table $t=(t_0,t_1,\ldots,t_{N+1})$ that fulfills the restrictions of definition 2.2.1 it holds: $t_i+c_{i,j}\le t_j$.

Convention

Proof of corollary 2.2.2 Case 1: $c_{i,j} \ge 0$ In this case task j begins at least $c_{i,j}$ after the beginning of task i. $\Rightarrow t_j \ge t_i + c_{i,j}$ Case 2: $c_{i,j} < 0$ In this case task i must begin at most $-c_{i,j}$ after the beginning of task j. $\Rightarrow t_i \le t_j + (-c_{i,j}) \Leftrightarrow t_i \le t_j + (-c_{i,j}) \Leftrightarrow t_i \le t_j - c_{i,j}$ $\Leftrightarrow t_i + c_{i,j} \le t_j \Leftrightarrow t_j \ge t_i + c_{i,j}$ Business Computing and Operations Research WINFOR 120

Consequences

Independent of its algebraic sign, distance requirements can be treated in the same way. Therefore, maximum and minimum distance restrictions are equivalent. This simplifies the following computations significantly.

Feasible time tables

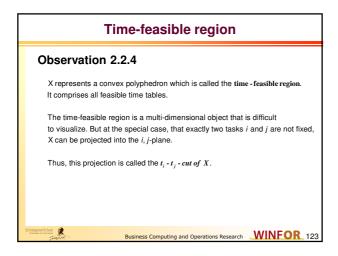

Definition 2.2.3

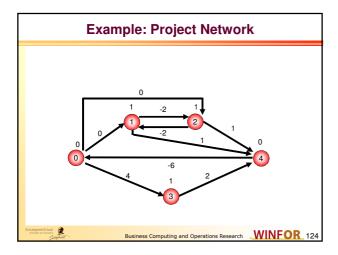

Let $V = (E,\Gamma,c)$ be a project task network, with $E = \{0,1,...,N,N+1\}$. Additionally, let T be a predetermined time bound for the maximum project duration. A time table $t = (t_0,t_1,...,t_N,t_{N+1})$ is **feasible** if and only if

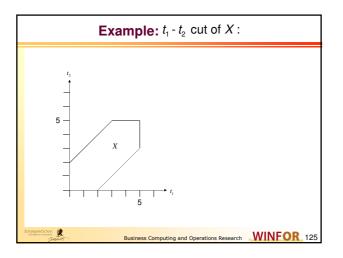

$$t \in X_{v}^{T} = X = \begin{cases} t \in IR_{\geq 0}^{N+2} / \\ \forall i \in \{0,1,\dots,N\} : \forall j \in \Gamma(i) : t_{j} \geq t_{i} + c_{i,j} \land \\ \forall i \in \{0,1,\dots,N+1\} : t_{i} \geq 0 \land t_{N+1} \leq T \end{cases}$$

Note that X_{V}^{T} (or X) defines the **set of feasible time tables**

Conclusion Corollary 2.2.5: The defined time restrictions in a project task network are transitive requirements, i.e., a valid time table fulfilling existing time restrictions defined by the arcs $(i,j,c_{i,i})$ and $(j,k,c_{i,k})$ fulfills also the time restriction defined by the arc $(i,k,c_{i,i}+c_{i,k}).$ The **proof** is trivial. Note that if there is a path p between two nodes i and jwith length $I_{i,j}(p)$, each feasible time table has to fulfill the restriction: $t_i \ge t_i + l_{i,j}(p)$. Also note that the longest path of a node *i* to itself is defined as I(i,i) = 0. rations Research WINFOR 126 2.3 Time analysis and planning Generation of feasible time tables We define: EB; Earliest possible beginning of task j in a feasible time table with respect to the project start which is set to the earliest beginning 0. LB_i : Latest possible beginning of task j in a feasible time table with respect to the project start and the restriction according to a maximum project duration. EE; Earliest possible end of task j in a feasible time table with respect to the project start which is set to the earliest

Computing EB values

 LE_i : Latest possible end of task j in a feasible time table with respect to the project start and the restriction according to a maximum project duration.

Business Computing and Operations Research WINFOR 127

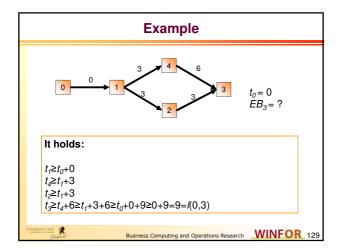

Lemma 2.3.1

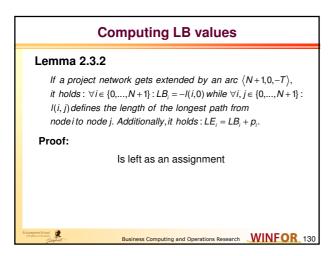

beginning 0.

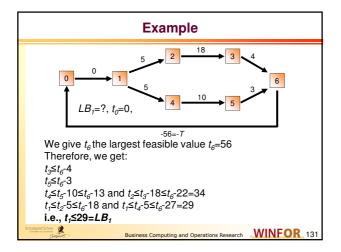

It holds: $\forall i \in \{0,...,N+1\}$: $EB_i = I(0,i)$ while $\forall i, j \in \{0,...,N+1\}: I(i,j)$ defines the length of the longest path from node i to node j. Additionally, it holds: $EE_i = EB_i + p_i$.

Assume t_i is the beginning of task i while all predecessors of i belong to the set $\Gamma^{-1}(i)$. In order to fulfill the existing time restrictions of the project, it holds for every path p with length $I_p^{i,i}$ starting at node j and ending at i: $t_i \ge t_j + l_p^{jj}$. Since node 0 is the start of the total project and t_0 the respective point of time, all paths from 0 to i define minimum distances according to the earliest beginning of task i. Therefore, by fulfilling the requirement of the longest path, all such restrictions are obeyed.

Conclusion

- In order to compute the values EB, LB, EE, LE for each task, we need an instrument to calculate the longest paths from an arbitrary node to the sink as well as from the source to an arbitrary node in the network
- Such an instrument is known as the so-called "Bellman-Ford algorithm" that works tree-oriented to generate one or all the longest paths starting from a predefined node to all other nodes in the network

Business Computing and Operations Research WINFOR 132

Bellman-Ford algorithm

Input: Network $V=(E,\Gamma,c)$ and node $i_0 \in E$

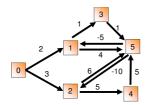

- Let $I(i_0)=0$ and iteration counter r=0. Additionally, B_0 is the tree comprising only node i_0 as its root If all leafs of B_r are labeled or have no successor in V, the algorithm stops. Otherwise, continue with step 3
- Starting with an unlabeled leaf i, consider all $j \in \Gamma(i)$
 - 1. j not in B_r : Insert j with $l(j)=l(i)+c_{i,j}$
 - j already in B, and $l(i)+c_{i,>}l(j)$: In sert j with the larger path length and label the old one with all successors

 - i already in B_r and l(i)+c_{i/}<l(j): Insert j as labeled leaf
 j already in B_r and l(i)+c_{i/}=l(j): Insert j with l(j) if and only if j does not lay on the given way from i₀ to i
 Increase r by 1; B_{r+j}=B_rU {new nodes in last round}
- Go to step 2

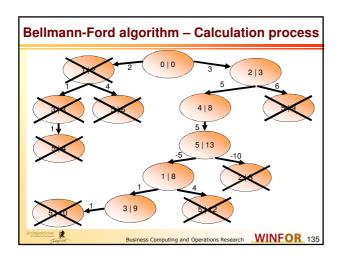

The algorithm has a time complexity of $O(|E|^*|\Gamma|)$.

Business Computing and Operations Research WINFOR 133

Business Computing and Operations Research WINFOR 138

We can state that the longest path from node 0 to node N+1 determines the shortest possible execution duration of the total project Therefore, we define all tasks belonging to this path as time-critical according to the shortest possible project execution duration Business Computing and Operations Research WINFOR 140

2.4 Analysis of the time table flexibility

- In what follows, we compute time windows for a later or earlier beginning of each task assuming a given time table
- These time windows elucidate the flexibility of the considered time table with respect of occurring disturbances during its realization
- The sizes of these time windows are often calculated by specific buffer times

Business Computing and Operations Research WINFOR 141

General time-table-oriented buffer times

- A fixed feasible time table $t \in X$ is predetermined
- Possible local relocations are considered
- We distinguish movements of the current task *i* beginning in direction of the project end from movements to the earliest position
- The first case is analyzed by the TFB_i(t)
- The second case is analyzed by the TBB_i(t)
- Changes of the positions of all other tasks by these movements of the beginning of task i are not allowed

Business Computing and Operations Research WINFOR 142

TFB_i(t) (Total Forward Buffer)

 $TFB_{i}(t) = t'_{i} - t_{i}$

while t_i^t defines according to plan t_i , the latest possible beginning of task i

i.e., it holds: $(t_0,...,t_{i-1},t_i^l,t_{i+1},...,t_{N+1}) \in X$

 $\Rightarrow t_i^I = \min\{T - p_i, t_j - c_{i,j} \mid j \in \Gamma(i)\}$

TBB_i(t) (Total Backward Buffer)

$$TBB_{i}(t) = t_{i} - t_{i}^{e}$$

while t_i^e defines according to plan t, the earliest possible beginning of task i

i.e., it holds: $(t_0,...,t_{i-1},t_i^e,t_{i+1},...,t_{N+1}) \in X$

$$\Rightarrow t_i^e = \max\{0, t_j + c_{j,i} \mid j \in \Gamma^{-1}(i)\}$$

chumpeter School of Business and Economics

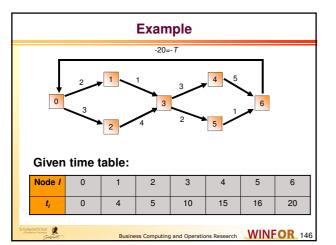

Business Computing and Operations Research WINFOR 144

Total time-table-oriented buffer time

• The total general time-table-oriented buffer time (*TB*_i(*t*)) is defined as follows:

$$TB_{i}(t) = TFB_{i}(t) + TBB_{i}(t)$$

Schumpeter School

$TFB_3(t)$, $TBB_3(t)$, $TB_3(t)$

- $TFB_3(t) = \min\{t_4-3, t_5-2, 20\} t_3 = \min\{12, 14, 20\} t_3 = 2$
- $TBB_3(t) = t_3 \max\{t_1 + 1, t_2 + 4, 0\} = 10 \max\{5, 9, 0\} = 1$
- $TB_3(t) = TFB_3(t) + TBB_3(t) = 2 + 1 = 3$

Business Computing and Operations Research WINFOR 147

Extreme buffer times

- While the time-table-oriented buffer times are computed according to the definitions of a given feasible time table, the extreme buffer times generate available time windows for each task in the best and in the worst case
- Therefore, extreme buffer times illustrate independently of a given time table which tasks have to be scheduled carefully to generate a reliable execution of the total project. We focus on the following topics:
 - Worst case consideration: Calculation of the time windows of each task in an adversarial situation defined by a specific time table $t_{worstcase} \in X$
 - Best case consideration: Calculation of the time windows of each task in an fortunate situation defined by a specific time table $t_{bestcase} \in X$
 - Therefore, all considered plans have to be feasible and belong to \boldsymbol{X}

Business Computing and Operations Research WINFOR 148

Minimal buffer time (MinB_i)

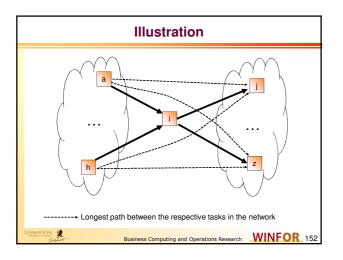

- Here we ask for the worst case, i.e., the minimum time window available for each task independent of a given time table
- By inserting the edge (*N*+1,0,-*T*), we integrate the restriction of the maximum project duration of T time units into the project task network
- Therefore, *MinB_i* is defined as follows:

 $MinB_i = min \{ TB_i(t) \mid t \in X \}$

Calculating the minimal buffer time (MinB_i) Lemma 2.4.1 The minimum buffer time $MinB_i$ may be computed by: $MinB_i = \min \left\{ l(h,j) - c_{h,i} - c_{i,j} \mid h \in \Gamma^{-1}(i) \land j \in \Gamma(i) \right\}$ Proof: The time window of each task i depends on the existing constellation of the respective predecessors and successors. Therefore, we have to consider $\Gamma(i)$ and $\Gamma^{-1}(i)$. Owing to the requirements of a feasible time table for each constellation $(h,j) \in \Gamma^{-1}(i) \times \Gamma(i)$ it holds: $t_h + l(h,j) \leq t_j.$

Business Computing and Operations Research WINFOR 150

Proof (continued): Therefore, each feasible time table t has to guarantee this minimum distance restriction between every constellation of predecessor and successor of i. This leads to the following lower bound for each time table $t \in X$: $TB_i(t) \ge \min\{I(h,j) - c_{h,j} - c_{i,j} \mid h \in \Gamma^{-1}(i) \land j \in \Gamma^{-1}(i)\}$. Therefore, we can conclude the defined calculation for MinB_i.

Maximal buffer time (MaxB_i)

- Here we ask for the best case, i.e., the maximum time window available for each task independent of a given time table
- By inserting the edge (*N*+1,0,-*T*), we integrate the restriction of the maximum project duration of T time units into the project task network
- Therefore, MaxB_i is defined as follows:

$$MaxB_i = \max \{ TB_i(t) \mid t \in X \}$$

Business Computing and Operations Research WINFOR 153

Calculation of MaxB_i

Lemma 2.4.2

The maximum buffer time $MaxB_i$ can be computed by:

$$MaxB_i = -\max\{l(j,h) + c_{h,i} + c_{i,j} \mid h \in \Gamma^{-1}(i) \land j \in \Gamma(i)\}$$

Proof:

Now we search for the constellation of $t \in X$ where i has the largest time window to be moved. Therefore, we have to ask for the maximum distance between all constellations of respective predecessors and successors. Consequently, we have to consider again $\Gamma(i)$ and $\Gamma^{-1}(i)$.

Business Computing and Operations Research WINFOR 154

Proof (continued):

Note that due to the attributes of a project task network it holds: $l(j,h) + c_{i,j} + c_{h,i} \le 0$. Therefore, we can compute the length of the maximum available time window by

 $TB_{i}(t) \le -\max\{l(j,h) + c_{i,j} + c_{h,i} \mid h \in \Gamma^{-1}(i) \land j \in \Gamma(i)\}.$

 \Rightarrow Consequently, we can derive the defined upper bound.

Owing to the requirements of a feasible time table for each constellation $(h, j) \in \Gamma^{-1}(i) \times \Gamma(i)$ it holds: $t_j + l(j, h) \le t_h$ and, as a result,

the maximum distance between these two tasks is restricted by $t_j - t_h \le -l \left(j,h\right)$. That means we have to search the most restrictive maximum distance restriction

between a successor and a predecessor of i.

Simple observations

- A small value for MaxB_i underlines that the task i can be seen as a very critical process in the project whose scheduling must be handled carefully
- In contrast to this, a large value for MinB_i can be seen as an indicator for an uncritical task

Schumpeter School of boiline are tremente	Business Computing and Operations Research	WINFOR	158

Attention

- In literature, four additional buffer times, which are introduced next, can be found
- But: Using these buffer times can lead to inconsistent results. Therefore, we do not concentrate our description to a pure definition but itemize additionally existing limitations for a possible application
- We characterize the following buffer times as specific time-table-oriented buffer times. This can be explained by the fact that their definition assumes the existence of an extreme constellation given by a specific time table. Unfortunately, this assumed plan is not always feasible, wherefore the computed times are not valid

Business Computing and Operations Research WINFOR 159

Total buffer time TBT_i

- The TBT; assumes the case where all successors of task i begin at their LB and all predecessors at their EB
- Computed by:

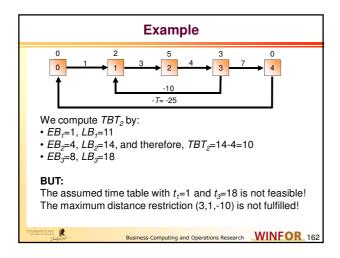

$$TBT_i = LB_i - EB_i$$

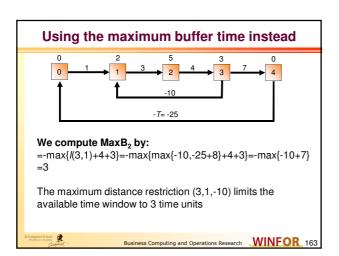

• The supposed extreme time table is not always **feasible**, i.e., the value of TBT_i is not always valid since it is not always possible to begin all predecessors at their EB and all successors at their LB. This plan can become infeasible

Business Computing and Operations Research WINFOR 160

Problems with TBT

- Closer analyses of the calculation of TBT; underline that the supposed constellation can lead to infeasible time tables if the project task network comprises a cycle of negative length after erasing the edge (N+1,0,-T)
- These cycles can define restrictive local requirements that are not respected by LB and EB and which are defined exclusively according to the longest path in the whole network. By neglecting these local requirements, the assumed time table can become infeasible

TBT vs. MaxB Lemma 2.4.3 If a project task network contains no cycle after erasing the edge (N+1,0,-T), it holds: $\forall i \in \{0,1,...,N,N+1\}$: $MaxB_i = TBT_i$ Proof: We assume that after erasing the edge (N+1,0,-T) the considered project task network does not contain any cycle. We compute $MaxB_i$ as follows: $MaxB_i = -max\{I(r,t) + c_{ir} + c_{ir}/t \in \Gamma^{-1}(i) \land r \in \Gamma(i)\}$ The computation defined above computes the length of a cycle in the network. Owing to our assumptions, this cycle always contains the edge (N+1,0,-T). Therefore, in this case we can derive: $MaxB_i = -(I(i,N+1) + I(0,i) - T) = \underbrace{T - I(i,N+1)}_{LB_i} - \underbrace{I(0,i)}_{EB_i} = TBT_i$ Business Computing and Operations Research WINFOR 164

Free buffer time (FBT_i)

- The FBT_i assumes that all predecessors and successors of task *i* begin to their *EB*
- Always applicable
- It holds:

$$FBT_i = TFB_i(t_{EB})$$

with: $t_{\it EB}$ defines the time table where each task i begins at $t_i = EB_i$

Business Computing and Operations Research WINFOR 165

Free backward buffer time (FBBT_i)

- The FBBT; assumes that all predecessors and successors of task i begin to their LB
- Always applicable
- It holds:

$$FBBT_i = TBB_i(t_{LB})$$

with: t_{LB} defines the time table where each task ibegins at $t_i = LB_i$

Business Computing and Operations Research WINFOR 166

Independent buffer time (IBT_i)

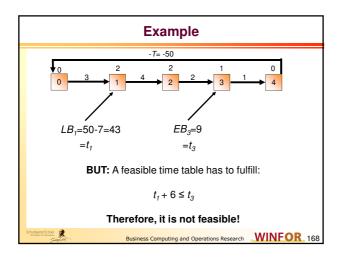

- The IBT_i assumes that all predecessors of task i begin at LB while ...
- ...all successors begin at EB
- An infeasible constellation is frequently defined by this parameter setting
- Therefore, for task *i* the so-called "independent interval" is generated as follows:

$$\forall i \in \{0, 1, ..., N, N+1\}: IPI_i = [t_i^i, t_i^n]$$

with:
 $t_i^i = \max\{LB_h + c_{h,i}lh \in \Gamma^{-1}(i)\}$ and
 $t_i^u = \min\{EB_i - c_{i,i}lj \in \Gamma(i)\}$

> If this interval is large, task i can be seen as an uncritical process in the project

Summary (buffer times)				
Characterization	Buffer time	Identifier	Comment	
General time- table-oriented	TT depending forward buffer	TFB(t)	Always valid	
buffer times	TT depending backward buffer	TBB(t)	Always valid	
	Sum of both	TB _i (t)	Always valid	
Extreme buffer times	Minimum buffer	MinB _i	Always valid	
, into	Maximum buffer	MaxB _i	Always valid	
Specific time- table-oriented	Total buffer	TBT _i	Only valid if the network contains no cycle	
buffer times	Free buffer	$FBT_{i}=TFB_{i}(t_{EB})$	Always valid	
	Free backward buffer	$FBBT = TBB(t_{LB})$	Always valid	
	Independent buffer	IBT _i	Frequently not valid
